A new algorithm for learning one-variable pattern languages from positive data is proposed and analyzed with respect to its *average-case* behavior. We consider the *total learning time* that takes into account all operations till convergence to a correct hypothesis is achieved. For almost all meaningful distributions defining how the pattern variable is replaced by a string to generate random examples of the target pattern language, it is shown that this algorithm converges within an *expected constant number of rounds* and a *total learning time* that is *linear* in the pattern length. Thus, our solution is average-case optimal in a strong sense. Though one-variable pattern languages can neither be finitely inferred from positive data nor PAC-learned, our approach can be extended to a *probabilistic finite learner* that *exactly* infers all one-variable pattern languages from positive data with *high confidence*. It is a long-standing open problem whether or not pattern languages can be learned in cases that *empty* substitutions for the pattern variables are also allowed. Our learning strategy can be generalized to this situation as well. Finally, we show some experimental results for the behavior of this new learning algorithm in practice. © 2000 Academic Press

## 1. INTRODUCTION

The formal definition of patterns and pattern languages goes back to Angluin [1]. Since then, pattern languages and variations thereof have been widely investigated (cf., e.g., [18, 19]). Patterns provide an intuitively appealing and natural way to define formal languages. Suppose you want to define the set of all strings of even positive length such that the first half is identical to the second half. In that case, the wanted language follows the pattern  $\pi = xx$ . Here  $x$  denotes a pattern variable, and the language generated by  $\pi$  is obtained by substituting any nonempty string for  $x$ . Note that this language is not context-free while the context-free language of the palindromes (the second half is the reverse of the first half) cannot be represented as a pattern language. Thus, pattern languages are somehow orthogonal to the Chomsky hierarchy.

As far as learning theory is concerned, pattern languages have attracted considerable attention during the past two decades (cf, e.g., [20], and the references therein). In particular, pattern languages are a prominent example of nonregular languages that can be learned in the limit from positive data (cf. [1]). The corresponding learning model goes back to Gold [10]. Let  $L$  be any language; then a *text* for  $L$  is any infinite sequence of strings containing eventually all strings of  $L$  and nothing else. The information given to the learner is successively growing initial segments of a text. Processing these segments, the learner has to output *hypotheses* about  $L$ . The hypotheses are chosen from a prespecified set called *hypothesis space*. The sequence of hypotheses has to *converge* to a correct description of the target language.

When looking at applications of limit learners, efficiency becomes a central issue. However, defining an appropriate measure of efficiency for learning in the limit is a difficult problem (cf. [17]). Various authors have studied the efficiency of learning in terms of the *update time* needed for computing a new *single* hypothesis. However, processing all initial segments quickly is by no means a guarantee to learn efficiently. What counts in applications is the overall time needed by a learner until convergence, i.e., the *total learning time*. Daley and Smith [5] developed general definitions for the complexity of inductive inference that essentially correspond to the total amount of computation time taken by a learner until successfully inferring the target. But if one allows the total learning time to depend on the length of all examples seen until convergence, then even a polynomially bounded total learning time does not guarantee efficient learning, since one may delay convergence until sufficiently long examples have been seen. On the other hand, the total learning time cannot be recursively bounded if it shall exclusively depend on the length of the target, but one allows arbitrarily adverse input sequences.

Valiant's PAC model [21] has resolved this problem by requiring a learner to find, with high confidence, a sufficiently good approximation from any randomly drawn sample of *adequate* size. What is adequate depends on the approximation and confidence parameters as well as on the VC dimension of the target class (cf. [2]). However, recently it has been shown that even the class of one-variable pattern languages has infinite VC dimension (cf. [15]). Thus, these languages are not PAC-learnable. As far as one-variable patterns are concerned, Kearns and Pitt

[11] have circumvented the problem of dealing with an infinite VC dimension by *a priori* bounding the length of substitution strings. This approach also works if the overall number of distinct variables occurring in a pattern is *a priori* bounded and if, additionally, the class of distributions is restricted to product distributions (cf. [11]).

This paper makes a rather different approach to design an efficient one-variable pattern language learner. Since the class of one-variable pattern languages is not PAC-learnable, we study their learnability in *the limit* and analyze the total learning time. Moreover, this complexity measure is taken with respect to the length of the target pattern. However, as the total learning time is *unbounded* in the worst-case, we concentrate on the *expected* total learning time.

Let us shortly summarize what has been known concerning the limit learnability of pattern languages. Angluin [1] provides a learner for the class of all pattern languages that is based on the notion of *descriptive patterns*. Here a pattern  $\pi$  is said to be descriptive (for the set  $S$  of strings contained in the input provided so far) if  $\pi$  can generate all strings contained in  $S$  and no other pattern with this property generates a proper subset of the language generated by  $\pi$ . Since no efficient algorithm is known for computing descriptive patterns, and finding a descriptive pattern of *maximum* length is  $\mathcal{NP}$ -hard, its update time is practically *intractable*.

Therefore, one has considered restricted versions of pattern language learning in which the number  $k$  of different variables is fixed; in particular, the case of a single variable. Angluin [1] gives an algorithm for computing one-variable descriptive patterns. The resulting learner for one-variable pattern languages has update time  $O(\ell^4 \log \ell)$ , where  $\ell$  is the sum of the length of all different examples seen so far. Nothing is known concerning the expected total learning time of her algorithm.

Erlebach *et al.* [6, 7] have presented a one-variable pattern learner achieving an average total learning time  $O(|\pi|^2 \log |\pi|)$ , where  $|\pi|$  is the length of the target pattern. This result is also based on finding descriptive patterns quickly. However, it is debatable whether descriptiveness of intermediate hypotheses should be the aim, since this may complicate the learning process and prevent an algorithm from processing the input sequences fast. Thus, we ask whether there are other strategies to learn one-variable pattern language with a significantly smaller expected total learning time—clearly, the best one can hope for is linear. Such a learner would be more appropriate for potential application than previous learners, even if there are fewer properties guaranteed for the intermediate hypotheses. With high probability, it will already have *finished* its learning task before any previously known learner has computed a *single* guess.

In this paper we present an optimal one-variable pattern learner. Moreover, we prove that our learner achieves an expected linear total learning time for a very large class of distributions with respect to which the input examples are drawn. But there is still the problem that, whenever learning in the limit is considered, the learner itself cannot decide whether or not it has already found the correct target. If convergence were decidable one would achieve finite learning (cf. [10]). But one-variable pattern languages are not finitely learnable from positive data. We resolve

this problem by establishing *exponentially shrinking tail bounds* for the expected total learning time. Then, requiring a bit of prior knowledge about the underlying probability distributions, we naturally arrive at *stochastic finite learning with high confidence*. Now, the learner gets a confidence parameter  $\delta$  as additional input. Depending on  $\delta$  and the information about the possible probability distributions it requests a certain number of examples, computes a pattern  $\pi$  from them as its *unique* hypothesis, and stops thereafter. By suitably modifying our learning strategy, we will show that with probability at least  $1 - \delta$  the hypothesis  $\pi$  is *exactly* correct for the target one-variable pattern language. The total amount of time taken is *linearly bounded* in the length of the target pattern and  $\log(1/\delta)$ .

Note that stochastically finite learning with high confidence is different from PAC-learning. First, it is not completely distribution independent. Thus, from that perspective, this variant is weaker than the PAC model. Nevertheless, some kind of distribution dependence is inevitable, since one-variable pattern languages are not PAC-learnable. On the other hand, the hypothesis computed is *exactly correct* with high probability. Moreover, the learner receives *exclusively* positive data while the correctness of its hypothesis is measured with respect to *all* data. Hence, from that perspective, our model of stochastic finite learning with high confidence is clearly stronger than the PAC model.

## 2. PRELIMINARIES

Let  $\mathbb{N} = \{0, 1, 2, \dots\}$  be the set of all natural numbers, and let  $\mathbb{N}^+ = \mathbb{N} \setminus \{0\}$ . For a real number  $y$  we define  $\lfloor y \rfloor$  the *floor function*, to be the greatest integer less than or equal to  $y$ . Let  $\Sigma$  be an alphabet with  $s := |\Sigma| \geq 2$ . By  $\Sigma^*$  we denote the free monoid over  $\Sigma$ , and we set  $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$ , where  $\varepsilon$  is the empty string. Let  $x$  be a symbol with  $x \notin \Sigma$ . Every string in  $(\Sigma \cup \{x\})^+$  is called a one-variable pattern. We refer to  $x$  as the pattern variable.  $Pat = Pat(\Sigma, x)$  denotes the set of all one-variable patterns. We write  $\#(\pi, x)$  for the number of occurrences of the pattern variable  $x$  in  $\pi$ .

The length of a string  $w \in \Sigma^*$  and of a pattern  $\pi \in Pat$  is denoted by  $|w|$  and  $|\pi|$ , respectively. Let  $w$  be a string with  $\ell = |w| \geq 1$ , and let  $i \in \{1, \dots, \ell\}$ ; by  $w[i]$  and  $w[-i]$  we denote the  $i$ th symbol in  $w$  counted from left to right and right to left, respectively, i.e.,

$$\begin{aligned} w &= w[1] w[2] \cdots w[\ell - 1] w[\ell] \\ &= w[-\ell] w[-\ell + 1] \cdots w[-2] w[-1]. \end{aligned}$$

For  $1 \leq i \leq j \leq \ell$  we denote the substring  $w[i] \cdots w[j]$  of  $w$  by  $w[i \cdots j]$ . Let  $\pi \in Pat$  and  $u \in \Sigma^+$ ; we use  $\pi[x/u]$  for the string  $w \in \Sigma^+$  obtained by substituting all occurrences of  $x$  in  $\pi$  by  $u$ . The string  $u$  is called a *substitution*. For every  $\pi \in Pat$  we define the *language generated by pattern  $\pi$*  by

$$L(\pi) := \{y \in \Sigma^+ \mid \exists u \in \Sigma^+, y = \pi[x/u]\}$$

and set  $PAT = \{L(\pi) \mid \pi \in Pat\}$ . Let, throughout this paper, the target pattern be grouped in the following form:

$$\pi = w_0 x^{\alpha_1} w_1 x^{\alpha_2} w_2 \cdots w_{m-1} x^{\alpha_m} w_m.$$

Here  $\alpha_i \in \mathbb{N}^+$  (the multiplicity by which  $x$  appears in a row), and  $w_i \in \Sigma^*$  denote the separating constant substrings, where for  $1 \leq i < m$  the  $w_i$  are assumed to be nonempty. Note that for  $\alpha_1 = 1$ ,  $m = 1$ , and  $w_0 = w_1 = \varepsilon$  we obtain the pattern  $x$ . This pattern is called *trivial*.

The learning problem considered in this paper is exact learning in the limit from positive data. Since we exclusively deal with the learnability of one-variable pattern languages, we specialize our definition of learning to this particular case. For a general definition of learning in the limit, the reader is referred to Gold [10].

A sequence  $(\psi)_{i \in \mathbb{N}^+}$  of patterns is said to *converge* to a pattern  $\pi$  if  $\psi_i = \pi$  for all but finitely many  $i$ .

**DEFINITION 1.** *PAT* is said to be *learnable in the limit* iff there is a learner such that for every  $L \in PAT$  and any sequence  $X_1, X_2, \dots$  of example strings from  $L$  the following holds. For each  $i \in \mathbb{N}^+$ , having received  $X_i$  the learner computes a hypothesis  $\psi_i \in Pat$  and the sequence  $(\psi_i)_{i \in \mathbb{N}^+}$  of guesses converges to a pattern  $\psi$  with  $L(\psi) = L$ .

Note that in the case of one-variable pattern languages, if  $L = L(\pi)$ , convergence to a correct hypothesis  $\psi$  implies that  $\psi = \pi$ . Some more remarks are mandatory here. Though our definition of learning resembles that given in Gold [10] and Freivalds *et al.* [8], there is also a major difference. In [8, 10] the sequence  $(X_i)_{i \in \mathbb{N}^+}$  is required to exhaust  $L(\pi)$  in the limit, that is, to fulfill  $\{X_i \mid i \in \mathbb{N}^+\} = L(\pi)$ . Nevertheless, in real applications this requirement will hardly be fulfilled. We therefore do not require this property here. Instead, we only assume that the sequence  $(X_i)_{i \in \mathbb{N}}$  contains “enough” information to recognize the target pattern  $\pi$ .

Intuitively, by “enough” we mean that all examples are drawn independently at random with respect to any probability distribution from a class of probability distributions that are supposed to fulfill the following *four* requirements. The class  $\mathcal{D}$  of distributions considered is defined over the set  $\Sigma^+$  of all possible substitutions. First, we require the *expected length* of substitutions (and hence of example strings) to be *finite*, since otherwise the expected learning time would be unbounded just due to reading data (cf. Assumption 1 at the end of this section). Second, the substitutions are not allowed to belong to any nontrivial one-variable pattern language; otherwise it is impossible (in the information-theoretic sense) to avoid over-generalization (cf. Assumption 2 in Section 3). Third, the *variance* of the substitution length must be *finite*, too, although this condition can be weakened somehow (cf. Assumption 3 in Section 4). Finally, there should be a *nonzero probability* to get substitutions that are *not* of the form  $sts$ ,  $s \in \Sigma^+$ ,  $t \in \Sigma^*$ , since such *symmetries* (as they will be called) cause difficulties to the learning algorithm (cf. Assumption 4 at the end of Section 4).

We continue with the complexity measure considered in this paper. The length of the pattern  $\pi$  to be learned is given by

$$n := n_w + n_x \quad \text{with} \quad n_w := \sum |w_i| \quad \text{and} \quad n_x := \sum \alpha_i.$$

This parameter  $n$  will be considered as the size of problem instances, and the complexity analysis will be done with respect to its value. We assume the same model of computation and the same representation of patterns as Angluin [1], i.e., in particular a random access machine that performs a reasonable menu of operations each in unit time on registers of length  $O(\log n)$  bits. The inputs are read via a serial input device, and reading a string of length  $\ell$  is assumed to require  $\ell$  steps.

In contrast to previous work (cf., e.g., [1, 12, 22]), we evaluate the efficiency of a learning algorithm by estimating the overall time taken by the learner until convergence (cf. [5]). This time is referred to as the *total learning time*. We aim to measure the total learning time with respect to the length of the target pattern. Of course, if examples are provided by an adversary the number of examples one has to see before being able to converge is unbounded in general. Thus, analyzing the total learning time in such a worst-case setting will not yield much insight. But such a scenario is much too pessimistic for many applications, and therefore, one should consider the average-case behavior with respect to distributions that occur in practice. Analyzing the expected total learning time of limit learners has been initiated by Zeugmann [23]. Since the average-case complexity in general depends highly on the distribution over the input space we like to perform our analysis for a large class of distributions.

Our main result, an optimal bound of linear expected total learning time, is achieved for basically all meaningful distributions. This linear bound can even be shown to hold with high probability. Let

$$\mu: \Sigma^+ \rightarrow [0, 1]$$

be the probability distribution defined over substitution strings. Thus,  $\mu$  specifies how the variable  $x$  is replaced in any given pattern  $\pi$  to generate random examples  $\pi[x/Z]$  from  $L(\pi)$ . Here  $Z = Z_\mu$  is a random variable with distribution  $\mu$ .

$$\text{Range}(Z) := \{w \in \Sigma^+ \mid \mu(x) > 0\}$$

denotes the range of  $Z$ , i.e., the set of all substitution strings that may actually occur. From this we get a probability distribution

$$\mu_\pi: \Sigma^+ \rightarrow [0, 1]$$

for the random strings generated by  $\pi$  based on  $\mu$ . Let  $X = X_{\pi, \mu}$  denote a random variable with distribution  $\mu_\pi$ . The random examples are then generated according to  $X$ ; thus, the relation between  $X$  and  $Z$  is given by

$$X = w_0 Z^{\alpha_1 w_1} Z^{\alpha_2 w_2} \cdots w_{m-1} Z^{\alpha_m w_m}.$$

Note that  $\mu$  is fixed and in particular *independent* of the target pattern to be learned. Furthermore, let  $\mathcal{X} = X_1, X_2, X_3, \dots$  denote a sequence of random examples that are independently drawn according to  $\mu_\pi$ . Finally, we let

$$L(\pi, \mu) := \{y \in \Sigma^+ \mid \mu_\pi(y) > 0\} = \text{Range}(X)$$

be the language of all example strings that may actually occur.

What we consider in the following is a large class  $\mathcal{D}$  of distributions  $\mu$  that is defined by requiring only very simple properties as outlined above by specifying what is meant by “enough.” This cannot be avoided because one can construct very biased distributions that hide information about the pattern at all or as long as one likes. We show that there exists a single algorithm that efficiently learns every one-variable pattern on the average with respect to every distribution in  $\mathcal{D}$ . Its strategy is based on a detailed analysis of the combinatorics of words generated by one-variable patterns. It is not required that the algorithm itself has any information about the underlying distribution; this will only be used in the analysis. Thus, unlike the PAC-model, the complexity bounds are not completely distribution-free. In contrast, as already mentioned, for the extension of this algorithm to a stochastic *finite* learner, some information about the distribution is necessary for the algorithm in order to compute the number of examples to be read.

By  $\mathbf{E}[|Z|]$  we denote the expectation of  $|Z|$ , the average length of a substitution. Then the expected length of an example string  $X$  for  $\pi$  is given by

$$E[|X|] = n_w + n_x \cdot E[|Z|] \leq n \cdot E[|Z|].$$

Obviously, if one wants to analyze the bit complexity of a learning algorithm with respect to the pattern length  $n$  one has to assume that  $E[|X|]$ , and hence  $E[|Z|]$ , is finite, otherwise already the expected length of a single example will be infinite.

*Assumption 1.*  $E[|Z|] < \infty$ .

### 3. PROBABILISTIC ANALYSIS OF SUBSTITUTIONS

For obtaining most general results we would like to put as few constraints on the distribution  $\mu$  as possible. As already mentioned one cannot learn a target pattern if only example strings of a very restricted form occur. This will be in particular the case if  $\text{Range}(Z)$  itself is contained in a nontrivial one-variable pattern language. For seeing this, suppose there exists a pattern  $\phi \in \text{Pat} \setminus \{x\}$  such that  $\text{Range}(Z) \subseteq L(\phi)$ . Clearly, then the languages generated by  $\pi = w_0 x^{\alpha_0} w_1 x^{\alpha_1} w_2 \cdots w_{m-1} x^{\alpha_m} w_m$  and  $\pi' = w_0 \phi^{\alpha_0} w_1 \phi^{\alpha_1} w_2 \cdots w_{m-1} \phi^{\alpha_m} w_m$  cannot be distinguished, since  $L(\pi, \mu) \subseteq L(\pi')$ . Thus, even from an information-theoretic point of view the learner has no chance to distinguish this case from the one where the pattern to be learned is actually  $\pi'$  and the examples are generated by the corresponding projection  $\mu'$  of  $\mu$ .

Hence, such a problem instance  $(\pi, \mu)$  should be regarded as the instance  $(\pi', \mu')$ . To exclude this case, let us define

$$p_0 := \max_{\phi \text{ pattern}, |\phi| > 1} \Pr[Z \in L(\phi)],$$

and let us make

*Assumption 2.*  $p_0 < 1$ .

An alternative approach would be to consider the correctness of the hypotheses computed with respect to the distribution  $\mu_\pi$ . The learner solves the learning problem for pattern  $\pi$  if it converges to a pattern  $\psi$  such that

$$\sum_{s \in L(\pi) \Delta L(\psi)} \mu_\pi(s) = 0,$$

where  $\Delta$  denotes the symmetric difference of sets. This model is equivalent, but conceptually more involved and would unnecessarily complicate the algorithm. To see the equivalence consider any target pattern  $\pi = w_0 x^{\alpha_0} w_1 x^{\alpha_1} w_2 \cdots w_{m-1} x^{\alpha_m} w_m$  and any substitution  $\mu$  such that  $\text{Range}(Z) \subseteq L(\phi)$  for some nontrivial pattern  $\phi$ . Furthermore, let  $\mu$  be such that all the conditions but the second one as discussed in the previous section concerning *enough information* are satisfied. Then, as we will show in Section 6, our learner infers the pattern

$$\psi = w_0 \phi^{\alpha_0} w_1 \phi^{\alpha_1} w_2 \cdots w_{m-1} \phi^{\alpha_m} w_m.$$

Now suppose  $\sum_{s \in L(\pi) \Delta L(\psi)} \mu_\pi(s) \neq 0$ . Since  $L(\psi) \subseteq L(\pi)$  there must be a string  $s \in L(\pi) \setminus L(\psi)$ , with  $\mu_\pi(s) > 0$ . Hence, there exists a substitution  $u$  with  $\mu(u) > 0$  such that  $s = \pi[x/u]$ . By the choice of  $\mu$ , we may conclude  $u \in L(\phi)$ , and therefore there has to be a substitution  $v$  with  $u = \phi[x/v]$ . Consequently,

$$x = w_0 \phi[x/v]^{\alpha_0} w_1 \phi[x/v]^{\alpha_1} w_2 \cdots w_{m-1} \phi[x/v]^{\alpha_m} w_m.$$

But this implies  $s \in L(\psi)$ , a contradiction.

Therefore we stick to the original definition. If  $p_0 < 1$  then the following quantities,

$$p_b := \max_{\sigma \in \Sigma} \Pr[Z[1] = \sigma],$$

$$p_e := \max_{\sigma \in \Sigma} \Pr[Z[-1] = \sigma],$$

are smaller than 1, too. Otherwise, for some  $\sigma \in \Sigma$  it would hold  $\text{Range}(Z) \subseteq L(\sigma x)$  or  $\text{Range}(Z) \subseteq L(x\sigma)$ . To illustrate these quantities, consider the special situation of *length-uniform distributions*, i.e., distributions where the lengths  $|Z|$  of the substitutions may be arbitrary, but for each length  $\ell$  all possible strings over  $\Sigma$  of that length have the same probability. Then it is easy to see that  $p_0 \leq 1/s$  and  $p_b = p_e = 1/s$ .

In general, define

$$p := \max\{p_b, p_e\} < 1,$$

and for sequences of substitutions  $\mathcal{Z} = Z_1, Z_2, Z_3, \dots$  the event

$$\begin{aligned} F_g[\mathcal{Z}] &:= [(Z_1[1] = Z_2[1] = \dots = Z_g[1]) \\ &\vee (Z_1[-1] = Z_2[-1] = \dots = Z_g[-1])]. \end{aligned}$$

Then

$$\Pr[F_g] \leq 2p^{g-1} - p^{2(g-1)}.$$

Moreover, we define  $f(\mathcal{Z}) := \min\{g \mid \neg F_g[\mathcal{Z}]\}$ , that is the smallest  $g$  such that the sequence of substitutions of the pattern variable reveals different symbols at the first position as well as at the last position.

LEMMA 1. *The expectation of  $f(\mathcal{Z})$  can be bounded as  $E[f(\mathcal{Z})] \leq 2/(1-p) - p^2/(1-p^2)$ .*

*Proof.* Clearly, if  $m < \min\{g \mid \neg F_g[\mathcal{Z}]\}$  then  $F_m[\mathcal{Z}]$  holds. Thus, we can estimate  $\Pr[f(\mathcal{Z}) > m] \leq 2p^{m-1} - p^{2(m-1)}$ , and a simple calculation yields

$$\begin{aligned} E[f(\mathcal{Z})] &= \sum_{m=0}^\infty \Pr[f(\mathcal{Z}) > m] \\ &\leq 2 + 2 \cdot \sum_{m \geq 2} p^{m-1} - \sum_{m \geq 2} p^{2(m-1)} \\ &= \frac{2}{1-p} - \frac{p^2}{1-p^2}. \quad \blacksquare \end{aligned}$$

4. SYMMETRY OF STRINGS

We now come to the main technical tool that will help us to detect the pattern variable and its replacements in example strings.

DEFINITION 2. Let  $y = y[1] \, y[2] \cdots y[\ell] \in \Sigma^+$  be a string of length  $\ell$ . If for some  $k$  with  $1 \leq k \leq \ell/2$  the  $k$ -length prefix and suffix of  $y$  are identical, that is,  $y[1 \cdots k] = y[\ell - k + 1 \cdots \ell]$ , we say that  $y$  has a  $k$ -symmetry  $u = y[1 \cdots k]$  (or symmetry, for short). A symmetry  $u$  of  $y$  is said to be *minimal* if its length is minimal among all symmetries of  $y$ . Let  $mls(y)$  denote this minimal length, and let  $sym(y)$  denote the number of different symmetries of  $y$ . For technical reasons, if  $y$  does not have a symmetry then we set  $mls(y) := |y| + 1$ .

DEFINITION 3. Let  $u$  be a symmetry of  $y$  and choose  $c, d \in \mathbb{N}^+$  maximal such that  $y = u^c v_0 u^d$ , for some string  $v_0$ ; i.e.,  $u$  is neither a prefix nor a suffix of  $v_0$ . This includes the special case  $v_0 = \varepsilon$ . In this case, since  $c$  and  $d$  are not uniquely determined, we choose  $c \geq d$  such that their difference is at most 1. This unique

representation of a string  $y$  will be called *factorization of  $y$  with respect to  $u$*  or simply  *$u$ -factorization*, and  $u$  the *base* of this factorization. If all occurrences of  $u$  are factored out including also possible ones in  $v_0$  one gets a representation

$$y = u^{c_0} v_1 u^{c_1} v_2 \cdots v_r u^{c_r}$$

with positive integers  $c_i$  ( $c_0 = c$ ,  $c_r = d$ ) and strings  $v_i$  that do not contain  $u$  as substring. This will be called a *complete  $u$ -factorization* of  $y$ .

Of particular interest for a string  $y$  will be its symmetry of minimal length, which gives rise to the *minimal factorization* of  $y$ .

The following properties will be important for the learning algorithm described later.

LEMMA 2. *Let  $k \in \mathbb{N}^+$  and let  $u, y \in \Sigma^+$  be any two strings such that  $u$  is a  $k$ -symmetry of  $y$ . Then we have*

- (1)  *$u$  is a smallest symmetry of  $y$  iff  $u$  itself has no symmetry.*
- (2) *If  $y$  possesses the factorization  $y = u^c v_0 u^d$  then it has  $k'$ -symmetries for  $k' = 2k, 3k, \dots, \min\{c, d\} \cdot k$ , too.*
- (3) *If  $\hat{u}$  is the minimal symmetry of  $y$ , that is,  $|\hat{u}| = mls(y)$ , and  $y = \hat{u}^c v_0 \hat{u}^d$  gives the corresponding minimal factorization, then up to length  $k' := \max\{c, d\} \cdot mls(y)$  there are no symmetries of  $y$  other than the ones listed in (2).*
- (4)  *$\text{sym}(y) \leq |y|/2 \cdot mls(y)$ .*

*Proof.* If a symmetry  $u$  of a string  $y$  can be written as  $u = u'vu'$  for a nonempty string  $u$  then obviously  $u'$  is a smaller symmetry of  $y$ . Hence, (1) follows.

Since  $u$  is a  $k$ -symmetry of  $y$ , we know  $|u| = k$ . Since  $y = u^c v_0 u^d$ , one immediately verifies that  $u^2, \dots, u^{\min\{c, d\}}$  are also symmetries having length  $2k, \dots, \min\{c, d\} \cdot k$ , and thus (2) is proved.

Next, let  $\hat{u}^c v_0 \hat{u}^d$  be the minimal factorization of  $y$ . By the definition of minimal symmetry,  $\hat{u}$  is the shortest string that is both prefix and suffix of  $y$ . Let  $mls(y) = |\hat{u}| = k$ . First observe that for any symmetry  $u$  with  $k \leq |u| \leq \max\{c, d\} \cdot k$  its length must be a multiple of  $k$ . Otherwise,  $u$  had to be of the form

$$u = \hat{u}^{c'} u' = u'' \hat{u}^{d'}$$

for substrings  $u'$  and  $u''$  with  $0 < |u'| = |u''| < k$ , and  $c' \leq c$  and  $d' \leq d$  with at least one of these inequalities being strict. But this implies that  $u'$  or  $u''$  is a proper substring of  $\hat{u}$  and hence, by the equality above,  $u' = u''$ . Then  $u'$  would be a smaller symmetry of  $y$  than  $\hat{u}$ .

It remains to consider the case  $\min\{c, d\} < \max\{c, d\}$  and a symmetry  $u$  of length  $\kappa \cdot k$  for some  $\min\{c, d\} < \kappa \leq \max\{c, d\}$ . Consider the case  $c < d$ , the other being symmetric. Then the factorization

$$y = \hat{u}^c v_0 \hat{u}^d = \hat{u}^\kappa \tilde{v} \hat{u}^\kappa$$

is not maximal since  $v_0$  contains as prefix another copy of  $\hat{u}$ . This proves (3).

If  $v_0$  contains  $u$  as a substring there may be other larger symmetries. For this case there must be strings  $v_1, v_2$  so that  $y$  can be written as

$$y = u^c v_1 u^d v_2 u^c v_1 u^d,$$

where  $v_1$  does not contain  $u$  as substring. Then  $y$  has an additional symmetry for  $k' = (c + d)k + |v_1|$ . There may be even more symmetries if  $v_2$  is of a very special form containing powers of  $u$ , but we will not elaborate on this further. The important thing to note is that the length of such symmetries grows at least by an additive term  $k = mls(y)$ . The bound on  $sym(y)$  follows. ■

Assertion (4) of the above lemma directly implies the simple bound

$$sym(y) \leq |y|/2,$$

which in most cases, however, is far too large. Only strings over a single letter can achieve this bound. For particular distributions the bound is usually much better. To illustrate this, we again consider the length-uniform case. Then, the probability that a random string  $y$  has a minimal symmetry of length  $k$  is given by

$$\Pr[mls(y) = k] = \Pr[|y| \geq 2k] \cdot s^{-k}.$$

Furthermore, given that  $mls(y) = k$  the probability that it has at least  $c$  symmetries is bounded by

$$\Pr[sym(y) \geq c \mid mls(y) = k] \leq s^{-k \cdot 2(c-1)} \cdot \frac{1}{1 - s^{-2c+1}}.$$

Thus, the probability of having at least  $c$  symmetries is at most

$$\sum_{k \geq 1} s^{-k \cdot (2c-1)} \leq \frac{s^{-2c+1}}{(1 - s^{-2c+1})^2}.$$

Now, we consider the expected number of symmetries. To motivate our Assumption 3, we first continue to look at the length-uniform case.

LEMMA 3. *In the length-uniform case*

$$E[sym(Z)] \leq \frac{s}{2(s-1)^2}.$$

*Proof.* Using the equality  $\sum_{c \geq 1} c \cdot \alpha^c = \alpha/(1 - \alpha)^2$  for  $\alpha = s^{-2k}$  in the estimation below one gets

$$\begin{aligned}
E[\text{sym}(Z)] &= \sum_{k \geq 1} \Pr[\text{mls}(Z) = k] \cdot \sum_{c \geq 1} c \cdot \Pr[\text{sym}(Z) = c \mid \text{mls}(Z) = k] \\
&\leq \sum_{k \geq 1} s^{-k} \sum_{c \geq 1} c \cdot s^{-k2(c-1)} \cdot \frac{1}{1 - s^{-2c+1}} \\
&\leq \sum_{k \geq 1} s^k \sum_{c \geq 1} c \cdot (s^{-2k})^c \cdot \frac{1}{1 - s^{-1}} \\
&= \frac{1}{1 - s^{-1}} \cdot \sum_{k \geq 1} s^k \cdot \frac{s^{-2k}}{(1 - s^{-2k})^2} \\
&\leq \frac{s}{2(s-1)} \sum_{k \geq 1} s^{-k} \\
&= \frac{s}{2(s-1)^2}. \blacksquare
\end{aligned}$$

Thus, in this case the number of symmetries only depends on the size  $s$  of the alphabet and therefore, it is independent of the length of the strings generated. Next, let us estimate the total length of all factorizations of a string  $y$ , which can be bounded by  $|u| \cdot \text{sym}(y)$ . In the length-uniform case, we get

$$\begin{aligned}
E[|Z| \cdot \text{sym}(Z)] &= \sum_{\ell \geq 1} \Pr[|Z| = \ell] \cdot \ell \cdot \sum_{k \geq 1} \Pr[\text{mls}(Z) = k \mid |Z| = \ell] \\
&\quad \cdot \sum_{c \geq 1} c \cdot \Pr[\text{sym}(Z) = c \mid \text{mls}(Z) = k, |Z| = \ell].
\end{aligned}$$

The estimation for  $E[\text{sym}(Z)]$  above is independent of the length of  $Z$ ; thus, the terms

$$\sum_{k \geq 1} \Pr[\text{mls}(Z) = k \mid |Z| = \ell] \cdot \sum_{c \geq 1} c \cdot \Pr[\text{sym}(Z) = c \mid \text{mls}(Z) = k, |Z| = \ell]$$

can be replaced by the bound for

$$\begin{aligned}
&\sum_{k \geq 1} \Pr[\text{mls}(Z) = k] \cdot \sum_{c \geq 1} c \cdot \Pr[\text{sym}(Z) = c \mid \text{mls}(Z) = k] \\
&\leq \sum_{k \geq 1} s^{-k} \sum_{c \geq 1} c \cdot s^{-k2(c-1)} \cdot \frac{1}{1 - s^{-2c+1}}.
\end{aligned}$$

This gives for  $E[|Z| \cdot \text{sym}(Z)]$  the same bound as for  $E[|Z|] \cdot E[\text{sym}(Z)]$ .

For arbitrary distributions, we require

*Assumption 3.*  $E[|Z| \cdot \text{sym}(Z)] < \infty$ .

Remember that we already had to assume  $E[|Z|]$  to be finite. Trivially, the expectation of  $|Z| \cdot \text{sym}(Z)$  is guaranteed to be finite if  $E[|Z|^2] < \infty$ ; that means the variance of  $|Z|$  is finite, but in general weaker conditions suffice.

If  $0 < E[|Z| \cdot \text{sym}(Z)] < \infty$  then we also have  $0 < E[\text{sym}(Z)] < \infty$ . Thus we can find a constant  $c$  such that

$$E[|Z| \cdot \text{sym}(Z)] \leq c \cdot E[|Z|] \cdot E[\text{sym}(Z)] = O(1).$$

Symmetries and factorizations should be computed fast; we thus show:

**LEMMA 4.** *The minimal symmetry of a string  $y$  can be found in  $O(|y|)$  operations. Given the minimal symmetry, all further symmetries can be generated in linear time.*

*From a symmetry, the corresponding factorization can be computed in linear time as well.*

*Proof.* To find the minimal symmetry we first compute a *maximal overlap* of  $y$ , that is, a substring  $w$  of maximal length such that

$$y = wv_1 = v_2w$$

for some nonempty strings  $v_1, v_2$ . If  $|w| \leq |y|/2$  then  $y$  can be written in the form

$$y = wvw$$

for some string  $v$ ; that means  $w$  is a symmetry of  $y$ . Since  $w$  was chosen maximal it is even the maximal symmetry. If  $|w| > |y|/2$  then in the representation  $y = wv_1 = v_2w$  the string  $w$  overlaps with itself; thus, it cannot be used as a symmetry. However, let  $\kappa$  denote the length of the  $v_i$ ,  $r = \ell - \kappa$  the length of  $w$ , and  $r' := \ell \bmod \kappa$ . Then

$$w[\kappa + 1 \dots r] = w[1 \dots r - \kappa],$$

which implies in particular  $w[1 \dots \kappa] = w[\kappa + 1 \dots 2\kappa]$ . In the same way,  $w[\kappa + 1 \dots 2\kappa] = w[2\kappa + 1 \dots 3\kappa]$ ; thus,  $w$  can be written as

$$w = w[1 \dots \kappa]^{\lfloor r/\kappa \rfloor} w[1 \dots r']$$

and

$$y = w[1 \dots \kappa]^{\lfloor r/\kappa \rfloor + 1} w[1 \dots r'],$$

where  $w[1 \dots r']$  is empty for  $r' = 0$ . Now define

$$w_0 := \begin{cases} w & \text{if } |w| \leq \ell/2, \\ w[1 \dots \kappa] & \text{if } r' = 0, \\ w[1 \dots r'] & \text{otherwise.} \end{cases}$$

Note that  $w_0$  is a symmetry of  $y$ . As already mentioned it is the maximal one in the first case, whereas in the other cases the maximal one is  $w[1 \dots \kappa]^{\ell/2\kappa}$  and  $w[1 \dots \kappa]^{(\ell-\kappa)/2\kappa} w[1 \dots r']$  for  $r' = 0$  and for  $r' > 0$ , respectively. Symmetries of size between  $w_0$  and the maximal one are of the form  $w[1 \dots \kappa]^L w[1 \dots r']$  for some  $1 \leq L < \ell/2\kappa$ . Having obtained  $w_0$ , iteratively in the same way we first compute the maximal overlap of this string and from this a substring  $w_1$ , and so forth until for the first time  $w_j$  has zero overlap. Then  $w_j$  is the minimal symmetry of  $y$ .

A maximal overlap (sometimes also called a maximal border) can be computed in linear time; see, for example, [4, Chap. 3.1], where an algorithm of complexity  $2|y| - 3$  is described.

Given the maximal overlap, the string  $w_0$  can easily be obtained in a linear number of steps. Since for all  $j$  the length of  $w_j$  is at most half the length of  $w_{j-1}$  the whole iterative procedure stays linearly bounded.

Once we have found a symmetry  $u$ , computing the complete  $u$ -factorization of  $y$  is just a simple pattern matching of  $u$  against  $y$ , which can be done by well-established methods in linear time.

From a complete minimal factorization based on  $u_1$  other symmetries can be deduced by checking the powers of  $u_1$  and the equality of substrings between these powers. This can be done in a linear number of operations. ■

Let  $\Sigma_{sym}^+$  denote the set of all strings in  $\Sigma^+$  that possess a symmetry and let

$$p_{sym} := \Pr[Z \in \Sigma_{sym}^+].$$

We require that the distribution is not restricted to substitutions with symmetries—with positive probability nonsymmetric substitutions should also occur.

*Assumption 4.*  $p_{sym} < 1$ .

Now consider the event

$$Q_g[\mathcal{Z}] := [\{Z_1, \dots, Z_g\} \in \Sigma_{sym}^+].$$

$Q_g[\mathcal{Z}]$  means that among the first  $g$  substitutions all have a symmetry. Obviously,

$$\Pr[Q_g[\mathcal{Z}]] \leq p_{sym}^g.$$

Define  $q(\mathcal{Z}) := \min\{g \mid \neg Q_g[\mathcal{Z}]\}$ . Similarly to Lemma 1, one can show

LEMMA 5.  $E[q(\mathcal{Z})] \leq 1/(1 - p_{sym})$ .

## 5. BASIC SUBROUTINES: FACTORIZATIONS AND COMPATIBILITY

For a subset  $A$  of  $\Sigma^*$  let  $\text{PRE}(A)$  and  $\text{SUF}(A)$  denote the maximal common prefix and suffix of all strings in  $A$ , respectively. Let  $m_{\text{pre}}(A)$  and  $m_{\text{suf}}(A)$  be their lengths. Remember that the target pattern has the form

$$\pi = w_0 x^{\alpha_1} w_1 x^{\alpha_2} w_2 \cdots w_{m-1} x^{\alpha_m} w_m.$$

Given a sequence of examples  $X_1, X_2, \dots$ , the first goal of the algorithm is to recognize the prefix  $w_0$  and suffix  $w_m$  before the first and last occurrence of the variable  $x$ , respectively, in the underlying pattern  $\pi$ . In order to avoid confusion,  $x$  will be called the *pattern variable*, where *variable* simply refers to any data variable used by the learning algorithm.

The current information about the prefix and suffix is stored in the variables PRE and SUF. The remaining pattern learning is done with respect to the current value of these variables. If the algorithm sees a new string  $X$  such that  $\text{PRE}(\{X, \text{PRE}\}) \neq \text{PRE}$  or  $\text{SUF}(\{X, \text{SUF}\}) \neq \text{SUF}$  then these variables will be updated. We will call this *the beginning of a new phase*.

**DEFINITION 4.** For a string  $Y \in \Sigma^+$  a (PRE, SUF)-factorization is defined as follows.  $Y$  has to start with prefix PRE and end with suffix SUF. For the remaining middle part  $Y'$  we select a symmetry  $u_1$ . This means  $Y$  can be written as  $Y = \text{PRE } u_1^{c_1} v_1 u_1^{d_1} \text{SUF}$  for some strings  $u_1, v_1$  and  $c_1, d_1 \in \mathbb{N}^+$ .

If such a representation is not possible for a given pair (PRE, SUF) then  $Y$  is said to have no (PRE, SUF)-factorization.

Moreover,  $Y'$  may have other symmetries  $u_2, u_3, \dots$  giving rise to factorizations  $Y = \text{PRE } u_i^{c_i} v_i u_i^{d_i} \text{SUF}$  for  $c_i, d_i \in \mathbb{N}^+$ . For simplicity, we assume that the symmetries  $u_i$  are ordered by increasing length; in particular  $u_1$  always denotes the minimal symmetry with corresponding minimal factorization.

**LEMMA 6.** Let  $Y = \text{PRE } u_1^{c_1} v_1 u_1^{d_1} \text{SUF}$  be the minimal (PRE, SUF)-factorization of  $Y$ . Then, for every string  $\tilde{Y}$  of the form  $\tilde{Y} = \text{PRE } u_1 \tilde{v} u_1 \text{SUF}$  for some string  $\tilde{v}$ , the minimal (PRE, SUF)-factorization of  $\tilde{Y}$  is based on  $u_1$ , too.

*Proof.* That  $u_1$  gives rise to a factorization is obvious. There cannot be one of smaller length because this implies that  $u_1$  has a symmetry and contradicts that  $u_1$  is minimal for  $Y$ . ■

Though the following lemma is easily verified, it is important to establish the correctness of our learner presented below.

**LEMMA 7.** Let  $\pi = w_0 x v x w_m$  be any pattern with  $\#(\pi, x) \geq 2$ ,  $w_0, w_m \in \Sigma^*$ , and  $v \in (\Sigma \cup \{x\})^*$ . Let  $u \in \Sigma^+$ , and let  $Y = \pi[x/u]$ . Then  $Y$  has a  $(w_0, w_m)$ -factorization with base  $u$  and its minimal  $(w_0, w_m)$ -factorization is based on the minimal symmetry  $u_1$  of  $u$ .

The results of Lemma 4 directly translate to

**LEMMA 8.** The minimal base for a (PRE, SUF)-factorization of a string  $Y$  can be computed in time  $O(|Y|)$ . All additional bases can be found in linear time. Given a base, the corresponding (PRE, SUF)-factorization can be computed in linear time as well.

**DEFINITION 5.** Two strings  $Y, \tilde{Y}$  are said to be *directly compatible* with respect to a given pair (PRE, SUF) if from their minimal (PRE, SUF)-factorizations a

single pattern  $\psi = \psi(Y, \tilde{Y})$  can be derived from which both strings can be generated. More precisely,

$$Y = \text{PRE } u_1^{c_1} v_1 u_1^{d_1} \text{SUF} \quad \text{and} \quad \tilde{Y} = \text{PRE } \tilde{u}_1^{\tilde{c}_1} \tilde{v}_1 \tilde{u}_1^{\tilde{d}_1} \text{SUF},$$

has to hold and for

$$Y_{\text{mid}} := u_1^{c_1-1} v_1 u_1^{d_1-1} \quad \text{and} \quad \tilde{Y}_{\text{mid}} := \tilde{u}_1^{\tilde{c}_1-1} \tilde{v}_1 \tilde{u}_1^{\tilde{d}_1-1}$$

every occurrence of  $u_1$  in  $Y_{\text{mid}}$ —including further ones in  $v_1$ —is matched in  $\tilde{Y}_{\text{mid}}$  either by an occurrence of  $\tilde{u}_1$  (which indicates that at this place  $\pi$  has a pattern variable) or by  $u_1$  itself (indicating that the constant substring  $u_1$  occurs in  $\pi$ ). In all the remaining positions  $Y_{\text{mid}}$  and  $\tilde{Y}_{\text{mid}}$  have to agree.

We extend this compatibility notion to pairs consisting of a string  $Y$  and a pattern  $\pi$ .  $Y$  is directly compatible to  $\pi$  with respect to (PRE, SUF) if for the minimal symmetry  $u_1$  of the (PRE, SUF)-factorization of  $Y$  holds  $\pi[x/u_1] = Y$ .

Let us add some remarks concerning this notion. Given its minimal symmetry, checking compatibility of a string  $Y$  against a pattern  $\pi$  is easy. If two strings  $Y, \tilde{Y}$  are directly compatible then there exists a pattern  $\pi$  such that  $\pi, Y$  are directly compatible as well as  $\pi, \tilde{Y}$ . The problem, however, is to find such a common  $\pi$  since a single string may be compatible to many different patterns.

The following lemma establishes the fundamental properties of this extended compatibility notion.

**LEMMA 9.** *Assume that  $(\text{PRE}, \text{SUF}) = (w_0, w_m)$  has the correct value. If a string  $Y$  is generated from  $\pi$  by substituting the pattern variable by a nonsymmetric string  $u$  then the string  $u_1$  on which its minimal (PRE, SUF)-factorization is based equals  $u$ . Thus,  $Y$  is directly compatible to  $\pi$ .*

*Proof.* It is easy to see that for a nonsymmetric string  $u$  the string

$$Y = \pi[x/u] = w_0 u^{\alpha_1} w_1 u^{\alpha_2} w_2 \cdots w_{m-1} u^{\alpha_m} w_m$$

has  $u$  as the basis for its minimal  $(w_0, w_m)$ -factorization. That  $u$  gives rise to a factorization is obvious, and if there were a smaller one it would imply that  $u$  has a symmetry. Since the constant substrings  $w_1, \dots, w_{m-1}$  may contain  $u$  as a substring the actual factorization may show more powers of  $u$ , but it is unique since occurrences of  $u$  cannot overlap—again because  $u$  is nonsymmetric. If the constant substring  $w_i$  of  $\pi$  has a decomposition with respect to  $u$  of the form  $u^{\beta_{i,0}} \omega_{i,1} u^{\beta_{i,1}} \cdots \omega_{i,n_i} u^{\beta_{i,n_i}}$ , where the  $\beta_{i,j}$  are integers and the  $\omega_{i,j}$  are substrings not containing  $u$ , then the middle part  $Y_{\text{mid}}$  of  $Y$  without prefix, suffix, and first and last occurrence of  $u$  looks like

$$u^{a_1-1} u^{\beta_{1,0}} \omega_{1,1} u^{\beta_{1,1}} \cdots \omega_{1,n_1} u^{\beta_{1,n_1}} u^{\alpha_2} u^{\beta_{2,0}} \omega_{2,1} u^{\beta_{2,1}} \cdots \omega_{2,n_2} u^{\beta_{2,n_2}} u^{\alpha_3} \cdots u^{\alpha_m-1}.$$

When checking direct compatibility of  $Y$  against  $\pi$  it becomes obvious whether a substring  $u$  in  $Y$  corresponds to a variable or not. ■

If one of the substitutions  $u, \tilde{u}$  for  $Y = \pi[x/u]$  and  $\tilde{Y} = \pi[x/\tilde{u}]$ , respectively, is a prefix of the other, let us say  $\tilde{u} = uu'$  for some nonempty string  $u'$  then there may be an ambiguity if  $uu'$  appears as a constant substring in  $Y_{\text{mid}}$ . If this is not followed by another occurrence of  $u'$  it can easily be detected. In general, if  $uu'$  is a constant in  $\pi$  then the number of occurrences following this substring will be the same in the corresponding positions in  $Y_{\text{mid}}$  and  $\tilde{Y}_{\text{mid}}$ ; otherwise it has to be one more in  $\tilde{Y}$ .

Using this observation it is easy to see that even in such a case testing of direct compatibility is easy.

**LEMMA 10.** *Let the minimal factorizations of two strings  $Y, \tilde{Y}$  be given. Then by a single joint scan one can check whether they are directly compatible and, if yes, construct their common pattern  $\psi(Y, \tilde{Y})$ . The scan can be performed in  $O(|Y| + |\tilde{Y}|)$  bit operations. Moreover, for a pattern  $\pi$  it can be checked in time  $O(|Y| + |\pi|)$  whether  $Y$  is directly compatible to  $\pi$ .*

The extra effort in the degenerated case of  $u$  being a prefix of  $\tilde{u}$  can be omitted if in this case the pattern matching is done from right to left since the procedure is completely symmetric. This will only fail if  $u$  is both prefix and suffix of  $\tilde{u}$ , implying that  $\tilde{u} = uu'u$ . But this means that  $\tilde{u}$  has a symmetry and thus cannot derive from a minimal factorization of  $\tilde{Y}$ .

**DEFINITION 6.** A string  $Y$  is *downward compatible* to a string  $\tilde{Y}$  with respect to a given pair (PRE, SUF) if for some  $\kappa \geq 1$ , from the minimal (PRE, SUF)-factorization of  $Y$  and the  $\kappa$ th (PRE, SUF)-factorization of  $\tilde{Y}$ , a single pattern  $\psi = \psi(Y, \tilde{Y}, \kappa)$  can be derived from which both strings can be generated. We also say that  $\tilde{Y}$  is *upward compatible* to  $Y$ .

Again, these notions are extended to pairs consisting of a string and a pattern.

**LEMMA 11.** *Assume (PRE, SUF) =  $(w_0, w_m)$ . Let  $Y = \pi[x/u]$  for a nonsymmetric string  $u$ . Any other string  $\tilde{Y}$  in  $L(\pi)$  obtained by substituting the pattern variable by a string  $\tilde{u}$  for which  $u$  is not a symmetry is upward compatible to  $Y$  with respect to (PRE, SUF). The pattern  $\psi(Y, \tilde{Y})$  equals the pattern  $\pi$  to be learned.*

*Given the (PRE, SUF)-factorization of both strings,  $\psi(Y, \tilde{Y})$  can be constructed in time at most  $O((1 + \text{sym}(\tilde{Y})) \cdot (|Y| + |\tilde{Y}|))$ , where  $\text{sym}(\tilde{Y}) := \text{sym}(\tilde{u})$  denotes the number of symmetries of the string  $\tilde{u}$  that generates  $\tilde{Y}$ .*

*Furthermore, given a pattern  $\psi$  and the factorization of a string  $Y$  it can be checked in time  $O(|Y| + |\psi|)$  whether  $Y$  is upward compatible to  $\psi$ . For  $Y$ , downward compatibility to  $\psi$  can be checked and  $\psi(Y, \psi, \cdot)$  can be constructed in linear time, too.*

*Proof.* Let  $u$  be nonsymmetric,  $Y = \pi[x/u]$ , and let

$$Y_{\text{mid}} = u^{\alpha_1 - 1} u^{\beta_1, 0} \omega_{1, 1} u^{\beta_1, 1} \dots \omega_{1, n_1} u^{\beta_1, n_1} u^{\alpha_2} u^{\beta_2, 0} \omega_{2, 1} u^{\beta_2, 1} \dots u^{\alpha_m - 1}.$$

If

$$\tilde{Y} = \pi[x/\tilde{u}] = w_0 \tilde{u}^{\alpha_1} w_1 \tilde{u}^{\alpha_2} w_2 \dots w_{m-1} \tilde{u}^{\alpha_m} w_m$$

then  $\tilde{Y}$  has a  $(w_0, w_m)$ -factorization based on  $\tilde{u}$ . Note that this factorization will not be minimal if  $\tilde{u}$  itself has symmetries. Since  $w_1, \dots, w_{m-1}$  may contain  $\tilde{u}$  the actual factorization may show more powers of  $\tilde{u}$ .

By assumption,  $u$  is not a symmetry for  $\tilde{u}$  and since one may either work from left to right or right to left we may assume that  $u$  is not a prefix of  $\tilde{u}$ . When comparing  $Y_{\text{mid}}$  to  $\tilde{Y}_{\text{mid}}$  after the first  $\alpha_1 - 1$  occurrences of  $u$  in  $Y_{\text{mid}}$  have been read and matched against occurrences of  $\tilde{u}$  in  $\tilde{Y}_{\text{mid}}$  the next occurrence of  $u$  in the substring  $u^{\beta_1, 0}$  will be detected as a constant. This is because this substring also occurs in  $\tilde{Y}_{\text{mid}}$  and  $u$  is not a prefix of  $\tilde{u}$ . The same holds for the other occurrences of  $u$  in  $Y$ .

Given the corresponding factorizations, checking whether  $Y_{\text{mid}}$  and  $\tilde{Y}_{\text{mid}}$  match can be done by a single pass over the strings and has linear time complexity. However, one has to find that factorization of  $\tilde{Y}$  that matches the one of  $Y$ . Considering the symmetries of  $\tilde{Y}$  in increasing length this will be symmetry  $\text{sym}(\tilde{u})$ . In the worst case, if  $\tilde{u}$  contains only one symbol  $\text{sym}(\tilde{u})$  can be as large as  $|\tilde{u}|/2$ , but such a case will be easier to handle.

This can even be sped-up. One observation is that a string with  $c$  symmetries yields at least by a factor  $c$  more occurrences of its minimal symmetry in the minimal factorization. Thus, once one output pattern  $\psi$  has been computed, which also gives the number of occurrences of the pattern variable, strings  $\tilde{Y}$  with a much larger number of occurrences in the minimal factorization based on a string  $\tilde{u}_1$  can simply be discarded unless  $\psi$  itself contains lots of substrings  $\tilde{u}_1$ . More precisely, let

$$\#(Y, u) := \text{maximal number of nonoverlapping occurrence of } u \text{ in } Y.$$

Since  $u$  is nonsymmetric and  $Y = \pi[x/u]$ ,

$$\#(Y, u) = \#(\pi, x) + \#(\pi, u).$$

For  $\tilde{Y} = \pi[x/\tilde{u}]$  and a symmetry  $\tilde{u}_i$  of a factorization of  $\tilde{Y}$  such that  $\tilde{u}_i$  is a substring of  $\tilde{u}$  it holds,

$$\#(\tilde{Y}, \tilde{u}_i) = \#(\tilde{u}, \tilde{u}_i) \cdots \#(\pi, x) + \#(\pi, \tilde{u}_i).$$

Let  $\psi$  be a pattern that is supposed to equal the pattern  $\pi$  to be learned. Thus, to find the right factorization of a string  $\tilde{Y}$  to check upward compatibility against  $\psi$  from the minimal factorization one can compute

$$\frac{\#(\tilde{Y}, \tilde{u}_1) - \#(\psi, \tilde{u}_1)}{\#(\psi, x)}$$

to get an estimate on  $\#(\tilde{u}, \tilde{u}_1)$ . When all symmetries of  $\tilde{Y}$  are known it is then easy to find that string  $\tilde{u}$  directly that matches this value. However, when checking upward compatibility of a string  $\tilde{Y}$  to a string  $Y$ , we do not have a precise estimate

on  $\#(\pi, x)$ , there is only the upper bound  $\#(Y, u)$  available from the factorization of  $Y$ . This implies a lower bound on  $\#(\tilde{u}, \tilde{u}_1)$  of the form

$$\#(\tilde{u}, \tilde{u}_1) \geq \frac{\#(\tilde{Y}, \tilde{u}_1) - \#(Y, \tilde{u}_i)}{\#(Y, u)}.$$

Thus, unless  $\#(\pi, u)$  is relatively large compared to  $\#(\pi, x)$ , this gives a good approximation of which symmetry of  $\tilde{Y}$  should be used. ■

Note that one cannot decide whether a string  $Y$  was generated by substitution with a nonsymmetric string by counting the number of its factorizations, which is likely to be one. However, there are rare cases with more factorization than the one induced by the substitution—for example, if  $\alpha_1$  and  $\alpha_m$  have a common nontrivial divisor or even if  $\alpha_1 = \alpha_m = 1$ , but by chance  $w_1 = uvv'$  and  $w_{m-1} = v''uv$  for some arbitrary strings  $v, v', v''$ .

## 6. LEARNING ONE-VARIABLE PATTERNS

Now, we are ready to present our one-variable pattern language learners. First, we describe the average-case optimal learning algorithm. Its correctness is established in Subsection 6.2. Then, we analyze its expected total learning time.

### 6.1. The Algorithm

The learner may not store all example strings encountered for further consideration.<sup>3</sup> Therefore, let  $A = A_g = A_g(\mathcal{X})$  denote the set of examples it remembers after having got the first  $g$  examples of the random sequence  $\mathcal{X} = X_1, X_2, \dots$ , and, similarly, let  $\text{PRE}_g$  and  $\text{SUF}_g$  be the values of the variables  $\text{PRE}$  and  $\text{SUF}$  at that time. We will call this *round*  $g$  of the learning algorithm.

Let us first describe the global strategy of the learning procedure. When the pattern is a constant  $\pi = w$  all example strings are equal to  $w$ . Thus, as long as the algorithm has seen only one string, it will output this string.

Otherwise, the learner first computes its actual guess for the prefix and suffix of the target pattern. Then we try to generate a pattern two compatible strings received so far. If this is not possible or if one of the examples does not have a factorization then the output will be the *default pattern*

$$\psi_0 := \text{PRE}_g \times \text{SUF}_g.$$

If a nondefault pattern has been generated as a hypothesis, further examples are tested for compatibility with respect to this pattern. As long as the test is positive the algorithm will stick to this hypothesis, otherwise a new pattern will be generated. In the simplest version of the algorithm we remember only a single example of the ones seen so far. Instead of a set  $A$  we will use a single variable  $Y$ .

<sup>3</sup> For the sake of completeness, it should be mentioned that we actually define our learner within the model given by Freivalds *et al.* [8].

## THE ONE-VARIABLE PATTERN LEARNING ALGORITHM.

```

 $Y := X_1;$ 
 $PRE := X_1;$ 
 $SUF := X_1;$ 
output  $X_1$ ;
for  $g = 2, 3, 4, \dots$ , do
   $PRE' := PRE$ ;  $SUF' := SUF$ ;
   $\psi :=$  output of previous round;
  read the new example  $X_g$ ;
  if  $X_g = \psi$ 
  then output  $\psi$ 
  else begin
     $PRE := PRE(\{PRE, X_g\})$ ;
     $SUF := SUF(\{SUF, X_g\})$ ;
    if  $PRE \neq PRE'$  or  $SUF \neq SUF'$  then begin
      compute the  $(PRE, SUF)$ -factorization of  $Y$ ;
       $\psi_0 := PRE \times SUF$ ;
       $\psi := \psi_0$  end
    endif;
    compute the  $(PRE, SUF)$ -factorization of  $X_g$ ;
    case 1:  $Y$  does not have a factorization
      then output  $\psi_0$ ;
    case 2:  $X_g$  does not have a factorization then begin
       $Y := X_g$ ;
      output  $\psi_0$  and  $Y := X_g$  end;
    case 3:  $\psi = \psi_0$  then begin
      if  $X_g$  is not larger than  $Y$  then  $Y := X_g$  endif
      if  $X_g$  is downwards compatible to  $Y$ 
        then output  $\psi(X_g, Y, \cdot)$ 
        else output  $\psi_0$  endif;
      end;
    case 4:  $X_g$  is upwards compatible to  $\psi$ 
      then output  $\psi$ ;
    case 5:  $X_g$  is downwards compatible to  $\psi$  then begin
       $Y := X_g$ ;
      output  $\psi(X_g, \psi, \cdot)$  end;
    else begin
      if  $X_g$  is not larger than  $Y$  then  $Y := X_g$  endif;
      output  $\psi_0$ 
    end
  end.

```

## 5.2. Proof of Correctness

Since the example strings are generated at random it might happen that only bad examples occur in which case no learning algorithm can eventually come up with

a correct hypothesis. However, the following claims will be true with probability 1. Remember that  $\pi = w_0 x^{\alpha_1} w_1 x^{\alpha_2} w_2 \cdots w_{m-1}^{\alpha_m} w_m$  is the pattern to be learned. Moreover, by Assumption 2,  $p_0 < 1$ , and thus  $p < 1$ , too. Consequently, not all randomly generated substitutions start with the same symbol or end with the same symbol. Therefore, with probability 1 a sequence  $\mathcal{X}$  contains strings  $X_i, X_j, X_k$ , where  $X_\kappa = \pi[x/u_\kappa]$  such that

$$u_i[1] \neq u_j[1] \quad \text{and} \quad u_i[-1] \neq u_k[-1].$$

Note that  $j$  may be equal to  $k$ . Let  $g$  be the maximum of  $i, j, k$  and consider a triple for which  $g$  is minimal. By the construction of the sets  $\text{PRE}$  and  $\text{SUF}$  round  $g$  will start a new phase in which now the variables  $\text{PRE}_g = w_0$  and  $\text{SUF}_g = w_m$  have the correct values.

We do not care about the output of the algorithm before this final phase has been reached. It remains to show that the algorithm will converge in the final phase. For this purpose, let us distinguish whether the pattern contains the variable only once, in which case there will be examples without any symmetry, or more than once (the case that the pattern does not contain any variable is obvious).

If  $\pi = w_0 x w_1$  then with probability 1 there will be an example  $X_g$  obtained from a substitution  $[x/u]$  with a nonsymmetric string  $u$ . Then  $X_g$  does not have a  $(\text{PRE}_g, \text{SUF}_g)$ -factorization and thus Case 2 occurs. Since  $Y$  is set equal to  $X$  from then on Case 1 always occurs. The algorithm will always choose Case 1 and output  $\psi_0$ , which in this case is the correct answer.

Otherwise, the pattern contains the variable at least twice and any example does have a  $(\text{PRE}_g, \text{SUF}_g)$ -factorization. Lemma 11 shows that a nonsymmetric substitution generates a string that is downward compatible to any other string in  $L(\pi)$ . Thus, as soon as  $X_g$  is such a string, which again happens with probability 1, the output  $\psi_g$  will equal the pattern  $\pi$ . Furthermore the algorithm will never change its output from this round on since Case 4 “ $X_{g'}$  is upwards compatible to  $\psi$ ” will hold for any  $g' > g$ . Let us summarize these properties in the following

**LEMMA 12.** *After the algorithm has detected the correct prefix and suffix it will converge immediately to the correct hypothesis  $\pi$  as soon it gets the first example generated by a nonsymmetric substitution.*

For the case that substitutions with large symmetries occur very frequently the algorithm can be modified to achieve convergence even before seeing a nonsymmetric substitution. For this purpose we perform a complete compatibility test in Cases 3 to 5 between the new example  $X_g$  and the string  $Y$  remembered as well as between  $X_g$  and the hypothesis  $\psi$ . This may increase the computational effort within one round, but reduces the number of rounds. This modification complicates the complexity analysis; therefore we will stick to the original version in the estimations below. For the experimental tests described in Section 8, however, we have used an implementation of this faster version in order to achieve convergence even for distributions with large symmetries, that is, for the case  $p_{\text{sym}} = 1$ .

### 6.3. Complexity Analysis of the Basic Algorithm

Let  $\psi_g$  denote the output of round  $g$ , and let  $Y_g$  denote the value of  $Y$  at the end of that round. Let  $Time_g(\mathcal{X})$  denote the number of bit operations in round  $g$  on example sequence  $\mathcal{X}$ , and recall that  $Z$  and  $X$  are defined as random variables for the substitutions and examples, respectively.

LEMMA 13. *For each round  $g$  it holds*

$$\begin{aligned} E[Time_g(\mathcal{X})] &\leq O(E[|X|] \cdot (1 + E[sym(Z)])) \\ &\leq O(n \cdot E[|Z|] \cdot (1 + E[sym(Z)])). \end{aligned}$$

*Proof.* By Lemmas 10 and 11 in each round  $g$  the number of bit operations can be estimated by

$$\begin{aligned} Time_g(\mathcal{X}) &\leq O(|Y_{g-1}|) + O(|X_g|) \\ &\quad + \max\{O((|Y_{g-1}| + |X_g|) \cdot (1 + sym(Y_{g-1}))), \\ &\quad O((|\psi_{g-1}| + |X_g|) \cdot (1 + sym(X_g))), O(|\psi_{g-1}| + |X_g|)\} \\ &\leq O(|Y_{g-1}| + |X_g| + |\psi_{g-1}|) \\ &\quad + |Y_{g-1}| \cdot sym(Y_{g-1}) + |X_g| \cdot sym(Y_{g-1}) \\ &\quad + |\psi_{g-1}| \cdot sym(X_g) + |X_g| \cdot sym(X_g). \end{aligned}$$

By construction of the algorithm and the fact that a pattern is never longer than an example string it generates we can bound  $E[|X_g|]$  as well as  $E[|Y_{g-1}|]$  and  $E[|\psi_{g-1}|]$  by  $E[|X|]$ . Moreover, Assumption 3 directly implies that  $E[|X_g| \cdot sym(X_g)]$  and  $E[|Y_{g-1}| \cdot sym(Y_{g-1})]$  are both bounded by  $O(E[|X|] \cdot E[sym(Z)])$ . Note, that  $X_g$  is independent of  $Y_{g-1}$  and  $\psi_{g-1}$ . Thus,

$$E[|X_g| \cdot sym(Y_{g-1})] = E[|X_g|] \cdot E[sym(Y_{g-1})] = E[|X|] \cdot E[sym(Z)]$$

and

$$E[|\psi_{g-1}| \cdot sym(X_g)] = E[|\psi_{g-1}|] \cdot E[sym(X_g)] \leq E[|X|] \cdot E[sym(Z)].$$

This simplifies the expectation to

$$\begin{aligned} E[Time_g(\mathcal{X})] &\leq O(E[|Y_{g-1}|] + E[|X_g|] + E[|\psi_{g-1}|]) \\ &\quad + E[|Y_{g-1}| \cdot sym(Y_{g-1})] \\ &\quad + E[|X_g| \cdot sym(Y_{g-1})] \\ &\quad + E[|\psi_{g-1}| \cdot sym(X_g)] \\ &\quad + E[|X_g| \cdot sym(X_g)] \\ &\leq O(E[|X|] + E[|X|] \cdot E[sym(Z)]). \quad \blacksquare \end{aligned}$$

Now we can also bound the total learning time.

LEMMA 14. *The expected total learning time is bounded by*

$$\begin{aligned} & O\left(E[|X|] \cdot (1 + E[\text{sym}(Z)]) \cdot \left(\frac{1}{1-p} + \frac{1}{1-p_{\text{sym}}}\right)\right) \\ & \leq O\left(n \cdot E[|Z|] \cdot (1 + E[\text{sym}(Z)]) \cdot \left(\frac{1}{1-p} + \frac{1}{1-p_{\text{sym}}}\right)\right). \end{aligned}$$

Since  $E[|Z|]$ ,  $E[\text{sym}(Z)]$ ,  $p$ , and  $p_{\text{sym}}$  are characterized by the distribution for substituting the pattern variable they are all independent of the problem size. This means the complexity grows linear with the size of the problem.

*Proof.* The number of rounds can be bounded by the number of rounds to reach the final phase plus the number of rounds in the final phase till  $\psi_g = \pi$ . By Lemmas 1 and 5 the expectation of both is a constant that only depends on the probabilities  $p$  and  $p_{\text{sym}}$ . Let  $G$  be a random variable that counts the number of rounds till convergence. Then,

$$E[G] \leq O\left(\frac{1}{1-p} + \frac{1}{1-p_{\text{sym}}}\right). \quad (1)$$

Let  $\text{Time}_{\text{total}}(\mathcal{X})$  denote the total number of operations on example sequence  $\mathcal{X}$ . Then

$$\text{Time}_{\text{total}}(\mathcal{X}) = \sum_{g=1}^G \text{Time}_g(\mathcal{X}) = \sum_{t \geq 2} \Pr[G=t] \cdot \sum_{g=1}^t \text{Time}_g(\mathcal{X})$$

and

$$\begin{aligned} & E[\text{Time}_{\text{total}}(\mathcal{X})] \\ & = E\left[\sum_{t \geq 2} \Pr[G=t] \cdot \sum_{g=1}^t \text{Time}_g(\mathcal{X})\right] \\ & \leq O\left(E\left[\sum_{t \geq 2} \Pr[G=t] \cdot t \cdot E[|X|] \cdot (1 + E[\text{sym}(Z)])\right]\right) \\ & \leq O\left(E[|X|] \cdot (1 + E[\text{sym}(Z)]) \cdot E\left[\sum_t \Pr[G=t] \cdot t\right]\right) \\ & = O(E[|X|] \cdot (1 + E[\text{sym}(Z)]) \cdot E[G]) \\ & \leq O\left(n \cdot E[|Z|] \cdot (1 + E[\text{sym}(Z)]) \cdot \left(\frac{1}{1-p} + \frac{1}{1-p_{\text{sym}}}\right)\right) \\ & = O(n). \quad \blacksquare \end{aligned}$$

Summarizing, we state the first main result of this paper.

THEOREM 1. *One-variable pattern languages can be inferred in linear expected total learning time for all distributions that fulfill the Assumptions 1 through 4 made above.*

Clearly, the expected value of a random variable is only one aspect of its distribution. Looking at potential applications of our learning algorithm, a hypothetical user might be interested in knowing how often the total learning time exceeds its average substantially. For answering this question we could compute the variance of the total learning time. Then Chebyshev's inequality provides the desired tail bounds. However, in our particular setting, there is an easier way to figure out how good the distribution of the total learning time is centered around its expected value, that is, proving *tail bounds*.

**THEOREM 2.** *For all  $\tau \in \mathbb{N}$  it holds:*

$$\Pr[Time_{total} \geq 2 \cdot \tau \cdot E[Time_{total}]] \leq 2^{-\tau}. \quad (2)$$

*Proof.* Our algorithm converges immediately when an example with a nonsymmetric replacement occurs. The expectation of this event is  $E[G]$ ; hence with probability at least  $1/2$  the algorithm converges within  $2E[G]$  rounds. If this has not happened no matter which bad examples have occurred, again there will be convergence in the next  $2E[G]$  rounds with probability at least  $1/2$ . ■

Since the distribution of  $Time_{total}$  decreases exponentially, all its higher moments exist. In particular, we may conclude that the variance of  $Time_{total}$  is small.

#### 6.4. Pattern Languages with Empty Substitutions

It is a long-standing open problem whether pattern languages with empty substitutions can be learned in the classical sense. Angluin's approach computing descriptive patterns does not work in this case. Our algorithm, however, is flexible enough to disregard certain examples temporarily and thus can solve this more difficult problem by the same strategy. The idea is to postpone the shortest example among all seen so far. This will guarantee that an example obtained by an empty substitution will never be processed, which otherwise would confuse the learner and prevent him from finding the correct pattern.

The modification uses an additional variable  $Z$  which stores the shortest string seen so far. For initialization the first two distinct examples  $X_1$  and  $X_j$  with  $j \geq 2$  are needed.  $Z$  is initialized to the shorter one or to  $X_1$ , respectively, if both have the same length (in this case neither  $X_1$  nor  $X_j$  are generated from an empty substitution and thus one could use both as well).  $Y$ ,  $PRE$ , and  $SUF$  are all initialized to the longer string, and then the for-loop starts with the next example  $X_{j+1}$ . At the beginning of each round the length of  $Z$  is compared with the new example, and they are exchanged in the case that the new example is shorter than  $Z$ . Up to round  $j-1$ ,  $X_1$  will serve as output. The hypothesis of the  $j$ th round is  $Y$ .

The correctness of this modified version follows easily from the analysis above. Since examples obtained from empty substitutions are never considered the modified algorithm will behave in the same way as the original one for a slightly modified sequence of examples, namely  $X_1, Y, X'_{j+1}, X'_{j+2}, \dots$ , where  $X'_{j+1}$  denotes the result after comparing  $X_{j+1}$  with  $Z$ . Since this is a possible sequence for the case without empty substitutions, for which we have proven correct convergence, this

holds for the modified version as well. The round of convergence, however, may be later. If the first nonsymmetric substitution  $X_g$  happens to be the shortest example seen so far it will be postponed. Thus we may have to wait for the second nonsymmetric substitution or a shorter string than  $X_g$ . Therefore, one can expect the modified algorithm to require at least one more round.

## 7. STOCHASTIC FINITE LEARNING

In this section, we convert the learning algorithm presented in Subsection 6.1 into a learner that identifies all one-variable pattern languages from positive data in a bounded number of rounds *stochastically finite with high confidence*. The additional ingredient needed is a certain amount of *additional knowledge* concerning the underlying class of probability distributions. Therefore, the resulting learning model is not distribution-free, and hence in this respect weaker than Valiant's [21] PAC model. On the other hand, one has to make certain assumptions on the class of probability distributions, since the one-variable pattern languages are not PAC-learnable (cf. [15]). But on the other hand, our model is stronger than the PAC model by requiring the output to be *exactly correct* with high probability. Moreover, the learner has to infer its hypotheses from positive data only, while the correctness of the output is measured with respect to all data, positive and negative. We continue with the formal definition.

**DEFINITION 7.** Let  $\mathcal{D}$  be a set of probability distributions on the learning domain, let  $\mathcal{C}$  be a concept class, let  $\mathcal{H}$  be a hypothesis space for  $\mathcal{C}$ , and let  $\delta \in (0, 1)$ .  $(\mathcal{C}, \mathcal{D})$  is said to be *stochastically finitely learnable with  $\delta$ -confidence* from positive data with respect to  $\mathcal{H}$  iff there is a learner that for every  $c \in \mathcal{C}$  and every  $D \in \mathcal{D}$  performs as follows. Given a random presentation  $\mathcal{X} = (X_j)_{j \in \mathbb{N}^+}$  for  $c$  generated according to  $D$ , the learner stops after having seen a finite number of examples and outputs a single hypothesis  $h \in \mathcal{H}$ . With probability at least  $1 - \delta$  (with respect to distribution  $D$ )  $h$  has to be correct; that is,  $h = c$ .

If stochastic finite learning can be achieved with  $\delta$ -confidence for every  $\delta > 0$  then we say that  $(\mathcal{C}, \mathcal{D})$  can be learned *stochastically finite with high confidence*.

Next, we specify the additional knowledge the learner must possess for learning stochastically finite with high confidence. Recall that the number  $G$  of rounds depends only on  $p$  and  $p_{\text{sym}}$ . Clearly,  $p$  and  $p_{\text{sym}}$  themselves are usually not known. But it is *reasonable* to assume the knowledge of *upper bounds* for both parameters. We therefore define the class  $\mathcal{D}[p^*, p_{\text{sym}}^*]$  of admissible probability distributions to be the set of all distributions fulfilling Assumptions 1 through 4 in a way such that  $p \leq p^*$  and  $p_{\text{sym}} \leq p_{\text{sym}}^*$ . Then, the following can be shown.

**THEOREM 3.** Let  $p^*, p_{\text{sym}}^* < 1$ , and let  $\mathcal{D}[p^*, p_{\text{sym}}^*]$  be a class of admissible probability distributions. Then  $(\text{PAT}, \mathcal{D}[p^*, p_{\text{sym}}^*])$  is *stochastically finitely learnable with high confidence from positive data using  $O(\log(1/\delta) \cdot |\pi|)$  many examples*.

*Proof.* First note that the learner gets  $\delta$  as additional input. In addition to the limit learner, it uses a counter for memorizing the *number* of examples already seen. The expected number of rounds is estimated by evaluating Formula 1 for  $p^*$  and

$p_{\text{sym}}^*$ . Let  $\tilde{G}$  be this estimate. Furthermore, the learner computes the least  $m$  such that  $2^{-m} \leq \delta$  and runs the basic algorithm for  $2 \cdot m \cdot \tilde{G}$  rounds. While doing this, no output is provided. After having finished these rounds, the learner outputs the last guess  $\pi$  made by the original algorithm and stops thereafter. Now, using the same argument as above for proving (2), one easily sees that  $\pi$  will be the correct target with probability at least  $1 - \delta$ . By construction the total learning time remains linear in the length of the pattern and  $\log_2(1/\delta)$ . ■

Finally, it should be noted that the number of rounds performed by our stochastic finite learner does *not* depend on the actual target to be learned but only on  $p^*$ ,  $p_{\text{sym}}^*$  and  $\log_2(1/\delta)$ . Thus, though our definition of stochastic finite learning with high confidence does not require this additional feature; it can be achieved for the one-variable pattern languages. Thus, we have a further resemblance to the PAC model.

## 8. EXPERIMENTAL DATA

Based on an implementation of the learning algorithm described and analyzed above and variants of this algorithm we have run a large amount of tests. For each choice of an instance of the one-variable pattern language learner, that is, for each pair of pattern and probability distribution for substituting the pattern variable, 100 experiments have been conducted.

The aim of this section is not to derive scientifically unassailable results from the experiments, or even to provide a rigorous interpretation within our mathematical setting. However, the experimental results support the parameters we have defined to classify the distributions and the information-theoretic assumptions made are appropriate. It is a challenging task to specify *real-world* distributions of pattern languages, and we hope that this task will be undertaken in the future; however, this task is beyond the scope of this paper. Rather, the experiments of this section aim solely to illustrate the influence of the parameters provided by our four assumptions, to give examples of problem instances for which pattern learning seems to be difficult (some kind of benchmark), and to point to some open problems.

The experimental results are given as Tables 1 and 2. These should be read as follows. Column 1 specifies the pattern. The second column gives the size  $s$  of the alphabet  $\Sigma$  used to replace the pattern variable.  $\Sigma$  was chosen as  $\{a, b, \dots\}$ .

The third column specifies the details of the distribution. For *length-uniform distributions* the notation  $[v, \mu]$  means that from the interval of natural numbers ranging from  $v$  to  $\mu$  each number was chosen with equal probability to be the length  $\ell$  of the substitution. Then, according to the definition of length-uniform, with equal probability for all strings in  $\Sigma^\ell$ , one was selected.

Distributions with symmetries,  $[v, \mu]$  mean that for the pattern variable  $x$  a string

$$w = y^k z y^k \in \Sigma^*$$

was randomly generated. Hereby,  $k$  is uniformly distributed in the interval  $[v, \mu]$ . Independently, the substrings  $y$  and  $z$  are selected length-uniformly. For the length

TABLE 1

Number of Rounds for the Learning Algorithm to Converge:  
Length-Uniform Distributions

Pattern	$ \Sigma $	Distribution	Average	Bound	Dominance	Maximum
Varying the pattern length						
$axbaxb$	2	[1,10]	3,73	8,00	3(29%)	9(1%)

Varying the alphabet size						
$axxbxxxxax$	3	[1,10]	3,04	5,00	2(39%)	8(1%)
$axxbxxxxax$	4	[1,10]	2,74	4,17	2(56%)	6(2%)
$axxbxxxxax$	10	[1,10]	2,34	3,35	2(76%)	6(1%)
Varying the example length						
$axxbxxxxax$	2	[5,5]	3,57	8,00	3(38%)	12(1%)
$axxbxxxxax$	2	[10,10]	4,00	8,00	3(27%)	8(4%)
$axxbxxxxax$	2	[20,20]	3,39	8,00	2(33%)	9(1%)
Very regular pattern						
$ax^{12}b$	2	[0,10]	3,66	8,00	3(27%)	9(1%)
$ax^{12}b$	4	[0,10]	2,63	4,17	2(54%)	6(1%)

of  $y$  the values from 1 to 5 are chosen with equal probability and for the length of  $z$  the values range from 0 to 5. However, in the case  $k = 0$ , that is  $w = z$ ,  $z$  has to be nonempty in order to avoid empty substitutions. The notation  $[3; 4; 6]$  means that the number  $k$  of symmetries is chosen equally likely among the values 3, 4, and 6.

Finally, for Markov chains, the substitution string  $x$  is generated by a random walk in the alphabet. In the uniform case the first symbol is chosen with equal

TABLE 2

Number of Rounds until Convergence: Distributions with Symmetries

$ax^{12}b$	2	[0,2]	5,72	7,00	2(21%)	21(1%)
$ax^{12}b$	2	[0,5]	5,93	10,00	3(25%)	25(1%)
$ax^{12}b$	2	[1,3]	5,44	$\infty$	3(18%)	16(2%)

FIG. 1. Complete distribution for test instance 3 and 2 of Table 1. (left) Pattern *abxbxxcxdaxxxbxb* with the  $[1, 10]$ -length-uniform distribution over the four letter alphabet. (right) Pattern *axxbxxax* with the  $[1, 10]$ -length-uniform distribution over two letters.

probability  $1/s$  among the elements of  $\Sigma$ . In the following steps of the random walk with probability  $1/(s+1)$  either another letter from  $\Sigma$  is chosen or the walk terminates. It is easy to see the expected length of  $w$  equals  $s+1$  in this uniform setting. We have also tested nonuniform random walks where some letters are much more likely to be the first and the last symbol of  $w$ , respectively, while others may not occur at all. For the distributions named *skewed 1* resp. *2*, see Figs. 3 and 4.

The distribution in Fig. 3, for example, has the property that substitutions beginning with the letters *ac* are very likely, while letter *c* will never occur at the beginning. At the end letter *b* is most likely, whereas *a* does not appear. Furthermore, a *b* will never be followed by a *c*.

FIG. 2. Uniform Markov chain distribution for alphabet size 4. In every node all outgoing edges have the same probability of being chosen.

FIG. 3. Markov chain distribution of type skewed 1. The probability in a given node to choose a particular edge is given by its weight divided by the sum of all weights of edges leaving this node.

FIG. 4. Markov chain distribution of type skewed 2.

FIG. 5. Complete distribution for test instance 6 and 4 of Table 2. (left) Pattern  $ax^{12}b$  for the distribution with a  $[0, 5]$ -symmetry over the two letter alphabet. (right) Pattern  $axxbxxxax$  with a  $[3; 4; 6]$ -symmetry over two letters.

FIG. 6. Complete distribution for test instance 1 and 4 of Table 3. (right) Pattern  $axxbxxxxax$  for the uniform Markov chain over the two letter alphabet. (left) The distribution given in Fig. 3 for three letters.

The fourth column gives the average number of examples the learning algorithm reads until its hypotheses have converged to the correct pattern that is, the average when observing the random variable  $G$  as defined in the proof of Lemma 14. Excluding the case of a trivial pattern without any variable,  $G$  is at least 2, and this value typically also occurs with high frequency.

The column labeled *bound* gives the numerical value of the upper bound estimation on  $G$  provided by Lemma 1 and 5. The sixth column labeled *dominance* gives the most frequent value of  $G$  that has occurred and its frequency in parenthesis, while the last column shows the maximal value of  $G$  and its frequency among the 100 test runs for this particular instance of the problem. If two values have occurred with the same frequency both values are listed (see the entries 2; 3 in the table). For some cases we also give the complete distribution of  $G$  in the following figures.

These data allow the following interpretation. First of all, the average number of rounds tends to be less than our estimated guarantees, in some cases much less. This can be explained by the fact that considering the probability  $p_{\text{sym}}$  is quite pessimistic. To receive an example with a nonsymmetric substitution is a sufficient condition for the algorithm to converge, but not a necessary one. If  $1/p_{\text{sym}}$  is large the actual behavior is significantly better than the upper bound derived from  $p_{\text{sym}}$ .

For alphabet size at least 3, the average of  $G$  is around 3 or less for uniform, distributions. This value is relatively independent of the pattern—its structure and length—and whether short examples (obtained by single letter substitutions) occur or not, compare the length uniform case where substitutions of length 20 only perform better compared to the case [1, 10] and [5, 5], for example. Even highly symmetric patterns like  $ax^{12}b$  are recognized very fast. Increasing the alphabet reduces the number of rounds slightly as should be expected.

For alphabets of size 2, however, about one additional example is needed, in particular for patterns like  $axxbxxxxax$ , where it is difficult to locate the positions that represent constants in the pattern. From the testing of many different patterns we got the impression that this pattern with an alphabet of size 2 belongs to the most difficult ones for the learning algorithm.

TABLE 3

Number of Rounds until Convergence: Markov Chain Distributions

Pattern	$ \Sigma $	Distribution	Average	Bound	Dominance	Maximum
$axxbxxxax$	2	uniform	3,84	8,00	3(27%)	13(1%)
$axxbxxxax$	4	uniform	2,70	4,17	2(51%)	5(4%)
$abxbxxcxdaxxxbx$	4	uniform	2,56	4,17	2(56%)	4(12%)
$axxbxxxax$	3	skewed 1	6,52	11,02	2(24%)	33(1%)
$axxbxxxax$	3	skewed 2	5,92	11,36	3(17%)	16(1%)

For heavily skewed distributions the number of rounds increases, which has to be expected. Even then, among the several thousands of runs conducted the maximal value having ever occurred was about 35 rounds, unless extremely biased distributions were chosen.

For this testing we have used an implementation of the algorithm that performs complete compatibility checking between pairs of strings. This increases the time within each round slightly if examples are highly symmetric, but will reduce the number of rounds. Even for certain distributions that generate only patterns with symmetries (the case  $[1, 3]$  and  $[3; 4; 6]$ ) this version is able to learn the pattern. For such cases our analysis above could not give any guarantee for convergence, indicated by the value  $\infty$  in the column labeled *bound*.

TABLE 4

Number of Rounds until Convergence of the Extended Algorithm with Complete Compatibility Checking and Empty Substitutions

Pattern	$ \Sigma $	Distribution	Average	Bound	Dominance	Maximum
length-uniform						
$axb$	2	$[0,10]$	4,92	9,09	4(30%)	10(2%)
$axbxab$	2	$[0,10]$	4,75	9,09	5(27%)	9(2%)
$axxbxxxax$	2	$[0,10]$	4,98	9,09	4(25%)	12(1%)
$ax^{12}b$	2	$[5,5]$	4,97	9,00	5(33%)	9(4%)
$ax^{12}b$	2	$[0,10]$	4,86	9,09	4(33%)	13(1%)
Markov chain						
$axxbxxxax$	2	uniform	5,30	9,33	4(28%)	13(1%)

Symmetries						
$axxbxxxax$	2	$[0, 3]$	4,71	11,05	3(26%)	10(1%)
$axxbxxxax$	2	$[1,3]$	4,78	$\infty$	4(32%)	12(2%)
$axxbxxxax$	2	$[3; 4; 6]$	4,75	$\infty$	3(27%)	10(2%)
$ax^{12}b$	2	$[0,2]$	5,03	8,07	4(24%)	10(1%)
$ax^{12}b$	2	$[1,3]$	4,62	$\infty$	4(29%)	12(1%)

Table 4 lists experimental results for a modified version of the learning algorithm that can also handle empty substitutions. Due to disregarding the shortest example this modified, version requires at least one more round. In addition, one has to take into account the probability for the learner to receive the empty substitution. We have included this delay in the upper bound estimations. Now, in the length-uniform case the value 0 for the length parameter  $\ell$  is also possible, and similarly for symmetric distributions. In the Markov chain model we add an edge that leads directly from the start node to the end node. The numerical data shown in Table 4 show the expected behavior when comparing it to the case without empty substitutions.

## 9. CONCLUSIONS

We have shown that one-variable pattern languages are learnable for basically all meaningful distributions within an optimal linear total learning time on the average. The algorithm obtained is quite simple and is based on symmetries that occur in such languages. Thus, our approach to minimize the expected total learning time turned out to be quite satisfactory.

Additionally, our learner requires only space for its long and short term memory that is linear in the length of the target pattern. Therefore, it is not only faster than the algorithms presented by Angluin [1] and Erlebach *et al.* [6] but also more space-efficient. The only known algorithm using even less space is Lange and Wiehagen's [12] learner. But their algorithm is only successful for a much smaller class of probability distributions, since it requires shortest examples in order to converge. As a matter of fact, our algorithm does not need shortest examples at all to achieve convergence. Its convergence is quite independent of the substitution length, which is further confirmed by our experiments.

On the other hand, our learner can easily be modified to maintain the *incremental* behavior of Lange and Wiehagen's [12] algorithm. Instead of memorizing the pair (PRE, SUF), it can also store just the two or three examples from which (PRE, SUF) has been computed. While it is no longer *iterative*, it is still a *bounded example memory* learner. A learner is called iterative if it uses only its last guess and the next example in the sequence of example strings for computing its actual hypothesis. A bounded example memory learner is additionally allowed to memorize an *a priori* bounded number of examples. For more information concerning these learning models, we refer the reader to Lange and Zeugmann [14].

Moreover, our algorithm not only possesses an expected linear total learning time, but also very good tail bounds. Note that, whenever learning in the limit is considered one cannot decide whether or not the learner has already converged to a correct hypothesis. If convergence is decidable, we arrive at *finite* learning. It is easy to see that one-variable pattern languages are *not* finitely learnable. On the other hand, a bit of prior knowledge about the underlying probability distributions nicely buys a *stochastically finite learner with high confidence* (cf. Theorem 3).

Note that stochastically finite learning with high confidence is different from PAC-learning. First, it is not completely distribution independent. Thus, from that perspective, this variant is weaker than the PAC model. On the other hand, since

the one-variable pattern languages are not PAC learnable (cf. [15]), one has to restrict the class of admissible probability distributions in one way or the other. Our restriction emerged quite naturally and comprises a huge class of probability distributions. Furthermore, the hypothesis computed is *exactly correct* with high probability. Moreover, the learner receives *exclusively* positive data while the correctness of its hypothesis is measured with respect to all data. Hence, from that perspective, our model of stochastically finite learning with high confidence is stronger than the PAC model.

Our approach also differs from U-learnability introduced by Muggleton [16]. First of all, our learner is fed with positive examples only, while in Muggleton's [16] model examples labeled with respect to their containment in the target language are provided. Next, we do not make any assumption concerning the distribution of the target patterns. Furthermore, we do *not* measure the expected total learning time with respect to a given class of distributions over the targets and a given class of distributions for the sampling process, but exclusively in dependence on the length of the target. Finally, we require exact learning and not a approximately correct learning.

Our implementation of the algorithm is available for public use through the WEB. The reader is referred to <http://www.tcs.mu-luebeck.de/Systeme.html> for getting access to the resulting Java-applets.

Next, we briefly discuss possible directions of further research. An obvious extension would be to consider  $k$ -variable pattern languages for small fixed  $k > 1$ . Already for  $k = 2$  the situation becomes considerably more complicated and requires additional tools.

Another direction to pursue would be to learn languages that are the union of at most  $\ell$  one-variable pattern languages for some fixed  $\ell$ .

Finally, the approach presented in this paper seems to be quite suited to tolerate errors in the example data. Let us assume that there is some (small) probability  $\varepsilon$  that

*error model 1:* in an example string  $X[1] \cdots X[l]$  a symbol  $X[i]$  is changed to a different one,

*error model 2:*  $X[i]$  is changed to a different symbol or removed or replaced by two symbols  $X[i] \sigma$  for some  $\sigma \in \Sigma$ .

A property of the pattern language like the common prefix of all strings now is only accepted if it is supported by a large percentage of examples. The details and modification of the algorithm will be given in another paper.
